Received 12 September 2001 / Accepted 15 October 2001  

Abstract. We present visible (BVRI) photometric measurements of 27 Trans-Neptunian objects, obtained with 
the FORS2 instrument on the ESO/8m Very Large Telescope (Unit 2) from runs during September and November 
2000. The objects display a broad and continuous range of colors from neutral-bluish to very red. Most of 
the objects also have a linear reflectivity spectrum over the VRI range. There is no evidence of a bimodal 
color distribution as has been previously reported by other groups. Several objects (1994 TB, 1995 SM5, 1998 UR33, 
1999CF115 and 2000 OK67) show evidence for changing color, and should be investigated further. The object 
1995 SM55 deserves a more complete study since its neutral-blue colors suggest it could be a good candidate for 
hosting cometary activity.

Key words. Edgeworth-Kuiper Belt – Trans-Neptunian Objects – Colors – Photometry – Reflectivity spectrum

1. Introduction

The region of the Edgeworth-Kuiper Belt, beyond the orbit of Neptune, is the origin of icy bodies that are 
among the most pristine solar system objects observable from Earth: Trans-Neptunian Objects (TNOs), which 
are still located in that region, and Centaurs, which are now found in the Saturn-Neptune region. The TNOs 
are subdivided into three dynamical classes: Classical objects (also called Cubewanos, due to the first object 
discovered 1992 QB1), Resonant objects (also named Plutinos, in reference to the most famous of them, Pluto) 
and Scattered Disk objects (Minor Planet Center, 2001b). Centaurs are now located closer to the Sun because of 
recent (i.e. within the last few million years; Levison, 2001) gravitational scattering by Neptune and the other 
giant planets, or ejection by collisions among TNOs. As of 11 September 2001, 431 TNOs (Minor Planet Center, 
2001c) and 79 Centaurs and Scattered Disk Objects (Minor Planet Center, 2001a) have been discovered 
maintly through dedicated search programs.

Studies of the physical nature of TNOs and Centaurs are based mostly on broadband colors and low-dispersion 
spectroscopy in the visible and near-IR. With the exception of the few largest objects, the only size estimates 
available are those computed from coarse single or two color photometry (necessarily assuming a value of the 
albedo, in general 4%, Keller, 1990) obtained by the search programs. More accurate multi-color photometry, 
suitable for a first taxonomic classification of the objects, is published for roughly 15% of the known TNOs and 
about 40% of the Centaurs: in absolute numbers, to date, 64 TNOs and 11 Centaurs (for a summary of the 
available results, discussions and references see Barucci et al. (1999) and Boehnhardt et al. (2001) or Hainaut 
& Delsanti (2001) for a more complete list). TNOs and Centaurs exhibit a broad range of colors, which may be 
indicative of the different processing of their surfaces. The existence of a bimodal color distribution (Tegler & 
Romanishin, 1998) appears to be controversial (Barucci et al., 2000; Davies et al., 2000; Boehnhardt et al., 2001; 
Hainaut & Delsanti, 2001). Distance and inclination dependent color diversities (Tegler & Romanishin, 2000; 
Trujillo et al., 2001) have not been firmly established yet, since they are based on small number statistics. 
Trends for a more complex surface color taxonomy of TNOs are indicated in a statistical color mode analysis.

* Based on observations performed with the Very Large Telescope facility of the European Southern Observatory at 
Cerro Paranal, Chile.
(Barucci et al., 2001). From the observations published for Centaurs (in total 11 objects) at best the likely color range can be estimated (Boehnhardt et al., 2001) and comparisons between the Centaurs and other populations (comets and TNOs) are not yet conclusive (Hainaut & Delsanti, 2001), although Boehnhardt et al. (2001) suggest that the spectral gradient population of TNOs and Centaurs may be different.

Spectra of TNOs and Centaurs are even more sparse in the literature; the spectra of TNOs in the visible (<10 objects) are featureless and their spectral slope is in agreement with the reddening predicted from the photometric colors of the objects (see Boehnhardt et al. (2001) and references therein, and Section 5.4 for a more detailed description of the reddening and how it is obtained). Most of the TNOs measured spectroscopically in the near-IR (~10 objects) display featureless spectra even though their reddening is very different from each other. However, absorption bands of water and hydrocarbons were found in one TNO in the near-IR (1996 TO6; Brown et al., 1997, 1999; Noll et al., 2000), but may also exist to a lesser extent in other TNO spectra (Brown, 2001). Five objects have been spectroscopically observed in both visible and near-IR (Barucci et al., 1999) and revealed mostly reflectance spectra. In the H and K band, water ice and tholin-like absorptions were also reported, such as for 1996 TO6 (Brown et al., 1999; Noll et al., 2000), or Pholus (Davies et al., 1993; Cruikshank et al., 1998). The identification of a very weak and wide silicate absorption from I to J band is tentative only (Cruikshank et al., 1998). In the case of Chiron, CN gas emission has also been detected at 388nm (Bus et al., 1991) in addition to the water ice absorption bands in the IR reported by Lun et al. (2000).

At present, it is still difficult to obtain conclusive results on the color taxonomy and the relationship between surface colors and spectral signatures of TNOs and Centaurs, since the number of objects measured is low and does not allow clear and statistically significant results.

In this paper we present new, accurate broadband color photometry of 24 TNOs and 3 Centaurs, as a significant contribution to the published data set; we discuss the individual observations of these objects and compare them to previously published data, when available.

2. Observations

The CCD photometry of TNOs and Centaurs was performed at the Very Large Telescope (VLT) facility of the European Southern Observatory in Chile. During two runs in Sep. and Nov. 2000, visible images of the objects through broadband filters were taken at Unit Telescope 2 (UT2) with the FOCal Reducer instrument (FORS2). For the BVI bands, Bessell filters were used. For the R band, a special interference filter was installed, to provide about the same central wavelength and equivalent bandwidth as the Bessel R filter, but with a slightly smaller transmission range with sharp wings, in order to avoid strong atmospheric emission lines. For details on the telescope and instrumentation, refer to E.S.O. (2001a,b). A summary of the observing conditions during both runs is given in Table 1.

The objects were selected for their observability, and their contribution to new and/or improved broadband colors in the visible and near-IR wavelength ranges. In addition, objects were selected such that there would be no bright (<16 mag) field stars near the expected target and with minimal field galaxy contamination. JHK photometry of a subset of the BVRI targets was executed simultaneously at the VLT telescope UT1 with the near-IR focal reducer instrument ISAAC. The results of the near-IR observations will be communicated and discussed in a separate paper (Boehnhardt et al., in preparation).

The BVRI exposures of a single object were typically executed within 20 to 60 minutes. For the short sequences, a set of RBVIR exposures were taken; for longer ones (more than 30 minutes) the R filter was repeated about every 30 minutes in between the whole filter series, in order to monitor possible rotational brightness variations of the object due to rotation. Sidereal tracking (which introduced a trailing < 0.6" i.e. of the order of the seeing during the observations), auto-guiding and full active optics corrections were used.

For the image calibration, standard star fields from Landolt (1992), sky flats and bias exposures were taken.

3. Data Reduction

The data were processed using MIDAS (Munich Image & Data Analysis System, E.S.O., 2000). The images were bias-subtracted and divided by a flat-field. The flat-field frame was either a combination of twilight flats or a “hyperflat”. For the first run (i.e. Sept 2000), the final flat-field used was simply a median frame of a series of normalized, bias-subtracted twilight flat-field images. For the second run, this could be further improved by a hyperflat-field frame created for each filter. The long science exposures were normalized to unit sky background and median averaged, to produce a night sky flat-field. We then combined the different orders of the wavelet transformation of i) the twilight median flat-field frame and ii) the night sky flat-field frame. This process allowed us to keep the best information on high and low frequencies of the twilight and night flat-field frames. This method is described in detail in Hainaut et al. (1998). At this stage, we did not correct images for bad columns or cosmic rays; instead, we prefer to only correct the blemishes present in the immediate neighborhood of the object when necessary.
Table 1. Summary of observing conditions for the 2 runs at ESO/Very Large Telescope. The objects observed during these runs are listed in Table 2.

4. Photometry

4.1. Classical Photometry

The photometric calibration was done using the MIDAS TMA package (Hainaut, 2001). The Landolt standard stars were measured using a large (i.e. 1.5' diameter) aperture. The zero point of the telescope, the extinction coefficients and the color correction terms were computed for each run by least square fit for the standard stars.

Using the MIDAS magnitude/circle function, the object was measured with an aperture diameter set to 4 times the stellar full width half maximum (FWHM) for each individual frame. This FWHM was evaluated on each image from several nearby, non-saturated stars. The sky background was measured in a 10 pixel (i.e. 2') wide annulus centered on the object, at ~6 FWHM from its center. The results obtained with this method, for all the objects, are summarized in Table 2.

For some of the faintest objects, the contribution of the sky background noise became important when using the default 4 FWHM diameter aperture. For these cases, we overcome this problem by using a 3 FWHM diameter aperture. The resulting magnitudes were not adjusted for an aperture correction and as we use these magnitudes for color study, the resulting colors are not affected either. The quantitative effect of this change is discussed in the next section.

4.2. Aperture correction

We performed an analysis of the aperture photometry in order to estimate the validity of the results from the previous section. To do so, we estimated the total magnitude of a high S/N star on each frame from the asymptotic value of its photometric growth profile. This value was compared in each case with that of the 4 FWHM aperture photometry. The correction appears to be constant from filter to filter and is estimated to be 0.03 magnitude for a 4 FWHM aperture. We therefore consider that the colors presented in this paper, resulting from the magnitudes listed in Table 2, are not affected by the aperture effect. However, it must be noted that the absolute magnitudes are too faint by ~3%.

5. Results

5.1. Color indexes

The resulting color indexes computed from the classical photometry measurements are shown in Table 3. For objects that have been measured at different epochs, we present one value per epoch in order to monitor any intrinsic brightness variation between the two runs. For objects which have repeated R measurements during the same night of observation, the colors are obtained from the average R.

5.2. Absolute magnitude

The absolute magnitude $M(1,1)$ has been computed for each epoch. It is defined as:

$$M(1,1) = R - 5\log(r\Delta),$$

(1)

where $R$ is the R magnitude, $r$ and $\Delta$ are respectively the helio- and geocentric distances [AU] at the time of the observations. We do not take into account the phase correction $-\beta\alpha$, where $\beta$ is the phase coefficient (cf Meech & Jewitt (1987) and Delahodde et al. (2001) for values of phase coefficient; a typical value is $\beta =0.04$ mag/°), and $\alpha$ is the phase angle. Indeed, $M(1,1)$ is used in this paper only for a rough estimation of the radius of the object, whose error is dominated by the albedo uncertainty.

As for color indexes, for objects with several epochs available, we present one value of the $M(1,1)$ obtained per epoch. In this way, we can improve our interpretation of any brightening or change between two epochs.

5.3. Radius

Assuming a canonical surface albedo of $p = 0.04$ (corresponding to that of cometary nuclei, Keller, 1990), we can estimate the radius $R_N[km]$ of each object. This value of the albedo is in agreement with thermal IR measurements obtained for TNOs by Thomas et al. (2000). $R_N[km]$ is computed with the following formula (Russell, 1916):

$$pR_N^2 = 2.235 \times 10^{16} \times 10^{0.4(M_\odot-M(1,1))},$$

(2)

where $M_\odot$ is the R magnitude of the Sun, $M(1,1)$ is the absolute R magnitude from Eq. 1 and $p$ is the albedo. The
Table 2. Magnitudes obtained for Run 1 and 2 using a fixed aperture diameter. \( r \) [AU] is the heliocentric distance at the epoch of the observations.

Notes: (1): Contamination by a nearby star. The magnitudes presented in this table have been corrected for this effect, (2): Possible variability, (3): Aperture diameter of 3 FWHM, (4): Object weak in B frame, (5): Bad seeing for some of the frames.
Fig. 1. Color-color diagrams for the 27 objects. The meaning of the different symbols is given in the middle right panel. The reddening line (which is the locus of objects displaying a linear reflectivity spectrum) has a range of gradients $S$ from $-10$ to $70\%/100\text{nm}$; a tick mark is placed at every 10 units.
values obtained are also presented in Table 3.

It is interesting to note that this radius, evaluated assuming an albedo \( p = 0.04 \), can be in error by a factor of 2 or more because of the uncertainty of this albedo. This is especially true for bluish objects, whose albedo could be fairly high (in the case of a fresh ice surface, i.e. 0.1 for Chiron, Hartmann et al., 1981), or very low (in the order of 0.02 in case of highly irradiated objects; Thompson et al., 1987). Therefore, this estimation of the radius has to be taken with precaution.

### 5.4. Spectral gradient

The color indexes can also be converted into relative spectral reflectivities \( \mathcal{R}(\lambda) \), computed at the central wavelength of the broadband filters used (Jewitt & Meech, 1986). We normalized these reflectivities at the central wavelength of the V filter, leading to the following equation:

\[
\mathcal{R}(\lambda) = 10^{-0.4[(m(\lambda)-m(V))-(m(\lambda)-m(V))_\odot]},
\]

where \( m \) and \( m_\odot \) are the magnitude of the object and of the Sun at the appropriate wavelength. In other words, the color indices are equivalent to very low resolution spectra. These spectra are presented in Fig. 2. To characterize a re-
Fig. 2. Reflectivity spectra. The reflectivity is normalized to 1 for the V filter; the “spectra” have been arbitrarily shifted for clarity. For each object, the dotted line is the linear regression over the V, R, I range (excluding B), corresponding to the gradient $S$ reported in this paper.

Reflectivity spectrum, we can consider the reddening, $S$ (also called the slope parameter or spectral index, cf. Hainaut 
& Delsanti, 2001), defined as percent of reddening per 100nm as:

$$S(\lambda_1, \lambda_2) = 100 \times \frac{R(\lambda_2) - R(\lambda_1)}{(\lambda_2 - \lambda_1)/1000}. \quad (4)$$

As most objects have a linear reflectivity spectrum over the V, R, and I bands, we can compute the mean reddening, $S$, by linear regression. All the values are presented in Table 3.

On each color-color plot we have represented a line which characterizes the locus of objects with a linear reflectivity spectrum, with reddening (i.e. spectral slope) ranging from $-10 < S < 70\%$/100nm, to guide the eye.

6. Discussion

This section compares our VLT data with those of merged sets compiled from the literature. It describes the possible group characteristics of the objects from color-color plots and outlines suggestions deduced from spectral gradient histograms of the objects.

6.1. Color-color plots

The color-color plots of the KBOs and Centaurs measured at the VLT (see Fig. 1) suggest the following:

The KBO color distributions appear to be rather uniform over the reddening range of $B-V \sim 0.55$–1.1 mag, $V-R \sim 0.35$–0.7 mag and $R-I \sim 0.3$–0.7 mag, respectively. A bimodal distribution (Tegler & Romanishin, 1998, 2000) is not at all obvious in our data. A similar conclusion on the likely absence of a bimodal $B-V$ versus $V-R$ distribution of KBOs is already mentioned by previous photometric studies (Barucci et al., 1999; Davies et al., 2000; Boehnhardt et al., 2001). The question of the bimodality is discussed in detail in Hainaut & Delsanti (2001) on the basis of the whole photometric database currently available (including those presented here) and with the help of different statistical tools. In summary, they demonstrate that, depending on the color index considered, there is either no bimodality at all, or that the limits of the bimodality are not statistically significant.

The reddening of the objects seems to be constant over the $B-V$ and $V-R$ wavelength range for a given object. Some objects show a deviation in the B band; it must however be noted that these deviations are compatible with the larger error bars, caused by a lower S/N ratio for the observations in this filter. The gradient systematically drops to smaller values for the $R-I$ color. This is indicated by (i) the close alignment of the data points with the reddening line (see Fig. 1) in the $V-R$ versus $B-V$ plot, and (ii) the drop of the data points below the line of constant reddening in the $R-I$ versus $B-V$ plot for the red objects. The latter effect suggests that the red objects have a flatter spectral gradient towards the far red and near-IR wavelength range while the neutral ones keep the reddening slope rather constant over the whole wavelength range measured. A
similar result was already reported by Boehmhardt et al. (2001).

6.2. Comparison of VLT data and merged dataset from literature

This paper’s dataset has been merged with a complete compilation of the TNO colors published in the literature (totalling ~ 100 objects); this compilation is presented and analyzed with a set of statistical tools in Hainaut & Delsanti (2001). In this section, we shall highlight some of the comparisons between the VLT observations presented here and the whole, multi-telescope, multi-observer dataset (of which this dataset represent about 25%).

Color-color diagrams and Dispersion of the data: The general aspect of the color-color diagrams is very similar. In particular, the reddest objects in the B-V, R-I and V-R, R-I also show a general trend to be lower than the reddening line (i.e. reflectivity spectrum less red at the longest wavelengths), as described in the previous paragraph. The general location and dispersion of the data is similar, indicating that both samples are compatible, i.e. no dramatic systematic effect is biasing some groups.

Outliers: Both samples show some outliers, i.e. objects located very far from the general flock of objects group around the reddening line. In particular, 1998 SN165, the most extreme outlier from our sample, was measured with similar colors by Gil-Hutton & Licandro (2001).

Bimodality and statistical tests: the sample we present here, as well as the merged dataset, do not present obvious bimodality in the color distribution. Hainaut & Delsanti (2001) have performed several statistical tests on the merged dataset, showing that there is no statistical support for a bimodal distribution (i.e. it is very unlikely that the observed distribution can be extracted from a bimodal distribution). The same tests, performed on this sample, would give the same negative result, but with a smaller significance.

6.3. Spectral gradient statistics on merged dataset

In Fig. 3, we show the distribution of the spectral gradients of KBOs and Centaurs. The histograms were compiled in the same way as described in Boehmhardt et al. (2001). The dataset used is composed of the measurements presented in this paper, combined with the input of Table 5 in Boehmhardt et al. (2001). The histogram bins are 10%/100nm wide which is the mean uncertainty of the object spectral gradients.

The bulk of KBOs falls into the reddening range of 0–40%/100nm with the maximum objects towards the red end of the distribution. The Centaurs may have a distinctly different distribution of spectral gradients, since the distribution “peaks” between 10–20%/100nm. Considering the three dynamical groups among KBOs separately, it is obvious that the Cubewanos resemble best the global trend in the spectral gradient histograms of all KBOs, while the Plutinos seem to follow more the Centaurs' trend, i.e. with a peak towards smaller reddening gradients. A second “population” of Plutinos has very red spectral slopes, while the range of the Cubewano peak is poorly occupied among the Plutinos. It is too early to draw conclusions about the group properties of scattered disk objects since only 8 objects have been measured so far. For the same reasons of low statistical significance, the suggestions concerning the Centaur and Plutino population distribution peaks have to be viewed with caution.
6.4. Surface processing

The evolution of the surface of the objects is probably the result of the balance of different processes. To date, the suspected processes are:

Aging: The surface of the objects, believed to be covered with organic-rich water ices, is irradiated by high-energy particles (cosmic rays ions, solar particles, etc) and undergoes a progressive darkening due to the loss of hydrogen atoms, polymerization, and to aromatization of the mantle (Sagan et al., 1984; Johnson, 2001; Moroz, 2001). The time-scale "for a significant radiolytic evolution of the optical surface of a Kuiper Belt Object can vary from millions of years in the region of highest anomalous cosmic ray (ACR) intensity to a billion years elsewhere due to the modulated galactic cosmic ray flux", Johnson (2001). The possible effect of radiation on reflectance depends also on the dose. An initial bright ice mixture, which displays neutral colors, high albedo and a flat visible spectrum, will evolve into a material with a red spectrum at medium dose. Subsequently, this could lead to a neutral dark material with a lower albedo and a flat spectrum at a higher dose (Johnson, 2001). An interesting question appears: can a surface element of an object remain undisturbed long enough to evolve from dark-red to neutral-black?

Collisions: Impacts on the surface (Stern, 1996) could modify the reflectance of the objects by excavating fresh material (i.e. non-irradiated, with a neutral reflectance spectrum) from the interior. The resulting color is then the average of the surface, including the undisturbed aged ice and the freshly excavated ice (Luu & Jewitt, 1996).

Cometary activity: The active area can present fresh ice, possibly mixed with a rubble mantle. It is also possible that dust trapped by the gravity of the objects will re-cover part or all of the non-active surface. The importance of cometary activity depends on the heliocentric distance of the object and on the thickness of the irradiated (and/or dust) mantle. However, observational evidence indicate that activity is routinely present at 15 AU (Meech, 1999). Activity could also be possible beyond 20 AU, as suggested by observations reported by Hainaut et al. (2000) and Fletcher et al. (2000) (although this result is only marginally significant), and by models presented by Prishik (2001).

These three processes affect either the objects as a whole (aging) or only a fraction of the surface (non-disruptive collisions). However, at all times of its evolution, an object surface element will present a straight reflectivity spectrum at visible wavelengths (cf laboratory spectra, Thompson et al., 1987). As a consequence, the average reflectivity spectrum of the object is also straight, explaining why all the objects are within their error bars on the reddening line (which represents the locus in a color-color plot of objects with a linear reflectivity spectrum).

6.5. Overview of the objects

In this section, we compare our color values with those reported in the literature. We also mention the other information available for these objects. This study is presented in Table 5; some additional comments can be found below for some of the objects.

1994 TB: There is a significant decrease of brightness by 0.25-0.30 magnitude between September and November (in R and I band), which is about 2 times the error bars. This could be due to rotational effects. To date, no light-curve has been published. We present the reflectivity spectra at the two different epochs in Fig. 4. It is also interesting to note that the colors and spectral gradient of the object changed significantly between the 2 epochs, suggesting a variegated surface. This object deserves a detailed multi-color light-curve.

1995 SM\text{55}: The absolute magnitude is marginally brightening by 0.07 magnitude (including a solar phase

effect correction of $-\beta/\alpha$ of 0.008 mag/°). The gradients are compatible between the two periods (cf Table 3).

It is interesting to note that Hillier et al. (2001) observed 1995 SM$_{55}$ several times in J band over the Oct. 1999-Jan. 2001 period. The object’s J light-curve is compatible with a constant, except for rapid variations (about 0.4 magnitude in a few hours) on 8 October 1999 and during January 2000, and for a brightening of almost 1 magnitude on 22 October, 1999. While the brightening could possibly be explained by midocic observing conditions, the authors affirm that the rapid changes seen over the January 2000 period are real and that they must correspond to a physical process occurring on the object.

Our observations, corrected for V–J, are compatible with the “quiescent” phase of the object. Considering the neutral-blush colors of the object, the short time-scale of the variations observed and their seemingly random behavior, 1995 SM$_{55}$ could possibly host some cometary activity, and deserves a detailed study.

1996 RQ$_{20}$: displays a marginally significant variability in R over half an hour.

1998 BU$_{46}$: No variability within the same night. Sheppard & Jewitt (2001) report a light-curve with an amplitude of 0.4 magnitude and a period larger than 4 hours.

1998 UR$_{43}$: Significant variation in R band of ~0.3 magnitude over ~1 hour suggesting a light-curve effect. Our V–R value is 0.13 lower than that of Gil-Hutton & Licandro (2001). As our measurements is right on the reddening line, it is possible that their color was affected by the rotation.

1999 CF$_{119}$: shows a variability of 0.1 magnitude in the R band over half an hour, suggesting a rotational effect.

1999 DE$_{9}$: Sheppard & Jewitt (2001) report a light-curve constant within 0.05 magnitude over few hours. Jewitt et al. (2000) reported a spectrum showing water ice features; however, this result has not been published yet.

1999 UG$_{5}$: A light-curve in R band has been published by Gutiérrez et al. (2001). The authors reported noticeable changes in brightness (0.2 mag) over 5 hours, which may be interpreted as the rotational light-curve (they cannot discriminate whether the variations are caused by the shape or by an albedo feature). Other causes are still possible, although cometary activity does not seem very likely.

2000 OK$_{47}$: The repeated observations in V band indicate a significant variation of 0.2 magnitude between the two runs.

6.6. Discussion

As explained in Section 5.4, the locus of objects with a linear spectrum (but with different spectral slopes) is the “reddening line” shown in the color-color plots (Fig. 1) for a slope $S$ ranging from −10 to 70%/100nm. The objects presented in this paper are located along this line (within their error bars, see Fig. 1), indicating that they display linear reflectivity spectra over the visible (VRI) wavelengths.

We could expect that an object undergoing an aging process caused by irritation (i.e., reddening of its surface, cf Section 6.4) may move along this line toward redder colors. At even higher irradiation dose, objects display a neutral but darker reflectivity spectrum (Thompson et al., 1987; Johnson, 2001), which means that they should move back down toward more neutral colors along this reddening line on the color-color plots. It is however unclear if a TNO can remain undisturbed long enough to evolve into a dark neutral colored object.

More generally, the possible path of a generic Kuiper Belt object in a color-color plot during its life has still to be determined, possibly by the modeling of the contribution of the different evolution processes involved (i.e., not only by the aging process). We can also consider that bluish objects are likely to be covered by fresh ice (in the case they are not covered by high-irradiated neutral-dark material Thompson et al., 1987), and are therefore more likely to host some cometary activity. As neutral objects could therefore have very young surfaces, with possible cometary activity, or very old surfaces with a very low albedo, we recommend observers to devote telescope time to these objects, especially with instruments that could directly measure their albedo (e.g., the thermal emission) such as SIRTF, or detect a cometary activity (e.g., very high spatial resolution with a large collecting area.)

7. Summary

We have presented the photometry of an important set of objects (24 TNOs and 3 Centaurs, which represent ~ 1/3 of the published objects to date) over the visible range (BVRI) from two run of observations (Sep. & Nov. 2000) with an 8m telescope (ESO/VLT). The objects display a broad and continuous range of colors from neutral-blush to very red, with no evidence of a bimodal color distribution. The distribution of the objects in the color-color plots shows that, within the error bars, the KBOs display linear reflectivity spectra over the visible (VRI) wavelengths.

Our measurements are compatible with those in the literature. For some of the objects, the availability of several epochs allowed us to detect some possible intrinsic changes such as for 1994 TB, 1995 SM$_{55}$, 1998 UR$_{43}$, 1999 CF$_{119}$ and 2000 OK$_{47}$. It appears that some objects
deserve a complete study such as 1995 SM₅₅ (to look for any possible cometary activity) or 1994 TB (for its spectral slope variability).

No further statistical test was performed on this dataset; a very detailed study of a larger sample including all published colors to date (including the data from this paper) is available in Hainaut & Delsanti (2001).
